## Track an Object in 3D space

Carlos E. Sanoja

### FP.1: Match 3D Objects

```
void matchBoundingBoxes(std::vector<cv::DMatch> &matches, std::map<int, int> &bbBestMatches, DataFrame
   int queryFrameIdx, trainFrameIdx;
   cv::KeyPoint queryFrame, trainFrame;
   int prevSize = prevFrame.boundingBoxes.size();
   int currentSize = currFrame.boundingBoxes.size();
   int counts[prevSize][currentSize] = { };
   vector<int> prevBoxIds, currBoxIds;
   // matched keypoints
   for(auto itl = matches.begin(); itl != matches.end(); ++itl )
        // save the id of every frame
       queryFrameIdx = (*itl).queryIdx;
       trainFrameIdx = (*itl).trainIdx;
       queryFrame = prevFrame.keypoints[queryFrameIdx];
       trainFrame = currFrame.keypoints[trainFrameIdx];
       prevBoxIds.clear();
       currBoxIds.clear();
        for(auto it2 = prevFrame.boundingBoxes.begin(); it2!= prevFrame.boundingBoxes.end(); ++it2)
            if((*it2).roi.contains(queryFrame.pt))
               prevBoxIds.push back((*it2).boxID);
        for(auto it2 = currFrame.boundingBoxes.begin(); it2!= currFrame.boundingBoxes.end(); ++it2)
            if((*it2).roi.contains(queryFrame.pt))
               currBoxIds.push_back((*it2).boxID);
        for(auto prevId:prevBoxIds)
            for(auto currId:currBoxIds)
               counts[prevId][currId]++;
   for (int i = 0; i < prevSize; i++)
        int max count = 0;
        int id max = 0;
        for (int j = 0; j < currentSize; j++)
            if (counts[i][j] > max_count)
                max count = counts[i][j];
                id max = j;
        bbBestMatches[i] = id_max;
```

### **FP.2 : Compute Lidar-based TTC**

In this part of the final project, your task is to compute the time-to-collision for all matched 3D objects based on Lidar measurements alone. Please take a look at the "Lesson 3: Engineering a Collision Detection System" of this course to revisit the theory behind TTC estimation. Also, please implement the estimation in a way that makes it robust against outliers which might be way too close and thus lead to faulty estimates of the TTC. Please return your TCC to the main function at the end of computeTTCLidar.

**Solution:** To deal with the outlier Lidar points in a statistically robust way to avoid serious estimation errors, here only the Lidar points within the ego lane are considered, and then the average distance to obtain a stable output is obtained. (**Fig 2**)

```
void computeTTCLidar(std::vector<LidarPoint> &lidarPointsPrev,
                     std::vector<LidarPoint> &lidarPointsCurr, double frameRate, double &TTC)
   vector<double> dPrev, dCurr;
   for (LidarPoint p : lidarPointsPrev)
       dPrev.push back(p.x);
    for (LidarPoint p : lidarPointsCurr)
       dCurr.push back(p.x);
   int size = dPrev.size();
   std::sort(dPrev.begin(), dPrev.end());
   double dt\theta = 0.0;
   if (size % 2 == 0)
       dt\theta = (dPrev[size / 2] + dPrev[size/2 - 1]) / 2;
       dt0 = dPrev[size / 2];
   double dt1 = 0.0;
   int sizel = dCurr.size();
   std::sort(dCurr.begin(), dCurr.end());
   if (sizel % 2 == 0)
       dt1 = (dCurr[size1 / 2] + dCurr[size1/2 - 1]) / 2;
       dt1 = dCurr[size1 / 2];
   double dt = 1 / frameRate;
   TTC = dt1 * (dt / (dt0 - dt1));
```

# FP.3 : Associate Keypoint Correspondences with Bounding Boxes

Before a TTC estimate can be computed in the next exercise, you need to find all keypoint matches that belong to each 3D object. You can do this by simply checking whether the corresponding keypoints are within the region of interest in the camera image. All matches which satisfy this condition should be added to a vector. The problem you will find is that there will be outliers among your matches. To eliminate those, I recommend that you compute a robust mean of all the euclidean distances between keypoint matches and then remove those that are too far away from the mean.

**Solution:** For each bounding box it is necessary to call this function, then scroll through all pairs of key points on the image. Then, when a key point is found within the region of interest, I associate that pair to the bounding box.

```
void clusterKptMatchesWithROI(BoundingBox &boundingBox, std::vector<cv::KeyPoint> &kptsPrev, std::vector<cv::KeyPoint> &kpts
    vector<double> distancias;
    for (cv::DMatch m : kptMatches)
       cv::KeyPoint prevPoints = kptsPrev[m.queryIdx];
       cv::KeyPoint currPoints = kptsCurr[m.trainIdx];
       distancias.push_back(sqrt(pow(prevPoints.pt.x - currPoints.pt.x, 2) + pow(prevPoints.pt.y - currPoints.pt.y, 2)));
   double meanDistance = accumulate(distancias.begin(), distancias.end(), 0.0);
   meanDistance /= distancias.size();
    double standarDev = 0.0;
    for (double d : distancias)
       standarDev += pow(d - meanDistance, 2);
    standarDev = sqrt(standarDev / distancias.size());
    for (int i = 0; i < kptMatches.size(); i++)
        if (abs(distancias[i] - meanDistance) < standarDev)</pre>
           boundingBox.kptMatches.push back(kptMatches[i]);
                                          Figure 3-. Cluster ROI function
```

### **FP.4**: Compute Camera-based TTC

Once keypoint matches have been added to the bounding boxes, the next step is to compute the TTC estimate. As with Lidar, we already looked into this in the second lesson of this course, so you please revisit the respective section and use the code sample there as a starting point for this task here. Once you have your estimate of the TTC, please return it to the main function at the end of compute TTCCamera.

**Solution:** Following the example given in the class, the distances between the key points are related and with it a TTC is estimated. It is perceived that the calculations obtained by this function sometimes present very different values to what they should be (as can be seen in table 2 marked in red) in the performance document.

```
// Compute time-to-collision (TTC) based on keypoint correspondences in successive images
void computeTTCCamera(std::vector<cv::KeyPoint> &kptsPrev, std::vector<cv::KeyPoint> &kptsCurr,
                     std::vector<cv::DMatch> kptMatches, double frameRate, double &TTC, cv::Mat *visImg)
    vector<double> distRatios;
    for (auto it1 = kptMatches.begin(); it1 != kptMatches.end(); it1++)
       cv::KeyPoint prevOutlier = kptsPrev[it1->queryIdx];
       cv::KeyPoint currOutlier = kptsCurr[it1->trainIdx];
        for (auto it2 = kptMatches.begin() + 1; it2 != kptMatches.end(); it2++)
           cv::KeyPoint prevInlier = kptsPrev[it2->queryIdx];
           cv::KeyPoint currInlier = kptsCurr[it2->trainIdx];
           double currentDistance = cv::norm(currOutlier.pt - currInlier.pt);
           double prevDistance = cv::norm(prevOutlier.pt - prevInlier.pt);
           if (prevDistance > std::numeric_limits<double>::epsilon() && currentDistance > 90)
                distRatios.push back(currentDistance / prevDistance);
    if (distRatios.size() == 0) {
    double dt = 1 / frameRate;
    int size = distRatios.size();
    std::sort(distRatios.begin(), distRatios.end());
    double medianDistRatio = 0.0;
    if (size % 2 == 0)
       medianDistRatio = (distRatios[size / 2] + distRatios[size/2 - 1]) / 2;
       medianDistRatio = distRatios[size / 2];
    TTC = -dt / (1 - medianDistRatio);
                                         Figure 4-. Camara TTC
```

#### **FP.5: Performance Evaluation 1**

This exercise is about conducting tests with the final project code, especially with regard to the Lidar part. Look for several examples where you have the impression that the Lidar-based TTC estimate is way off. Once you have found those, describe your observations and provide a sound argumentation why you think this happened.

**Solution:** The lidar can be considered one of the safest sensors for this type of calculation because of the way it calculates TTC. However, there are imperfections, especially when trying to

eliminate outliers. Due to multiple causes that can be hardware or software, such as vibrations, lack of calibration, which affects the TTC calculation and causes the difference in seconds to vary. Therefore, one of the possible solutions could be to try different clustering methods, combining different sensors to obtain a better time estimate.

## **FP.6: Performance Evaluation 2**

This last exercise is about running the different detector / descriptor combinations and looking at the differences in TTC estimation. Find out which methods perform best and also include several examples where camera-based TTC estimation is way off. As with Lidar, describe your observations again and also look into potential reasons. This is the last task in the final project.

**Solution:** To appreciate the graph correctly, the very large values were limited to +100,-100. So in table 1 you can see all the TTC values for each combination and analyze the differences and similarities of each of them. One of the main causes may be that the matching of points between the frames was incorrect. Contrast between images, lighting, etc.
